WEATHER AND CLIMATE EXTREMES IN LIGHT OF THE IPCC SREX (2011) AND BEYOND

JÁNOS MIKA[1]

ABSTRACT. Weather and climate extremes in light of the IPCC SREX (2011) and beyond. The recent IPCC Special Report (IPCC SREX, 2011) provides a comprehensive overview of meteorological (i.e. weather and climate) extremes and their various aspects. The present paper reflects the core concepts of the Report, clarifying the relations of the natural and anthropogenic factors causing meteorological extremes, as well, as condition determining the risks and general ways of response by the society. The paper can only add some recent statistics to this scheme on various aspects of meteorological and non-meteorological reasons of natural disasters. The paper argues, however, the still unclear definition of the extremes and their classification as weather and climate extremes. We also dedicate a sub-Section to the statistical and physical considerations on how the extremes may change parallel to the global warming. Another sub-Section refers to further difficulties that hamper the empirical establishment of the trends in the meteorological extremes. Finally we overview the IPCC AR4 (2007) conclusions on some meteorological extremes, since the detailed Chapters of the IPCC SREX (2011) Report were not available by the time of writing the paper, but from its SPM no difference in the statements and even its uncertainties can be established since the AR4.

Keywords: weather extreme, climate extreme, natural disaster, climate change.

1. INTRODUCTION

The *impact areas* of extreme meteorological events cover wide ranges (e.g. Gyuró et al., 2007). The disadvantageous impacts of extreme meteorological events include: floods, excess inland water inundations, droughts, rainstorms, hails, heat waves, increasing UV radiation, early and late frosts, snow jams, wind storms, forest and bush fires, appearance of new pathogens and pests.

There is little doubt that society as a whole has become more sensitive to extreme weather, since population and infrastructure continues to grow in areas that are vulnerable to the weather and climate extremes. As it is seen in *Fig. 1*, weather extremes play a sorrowful important role among the natural disasters in global and in European comparison, especially concerning the economical losses.

According to these Figures, the reasons not related to meteorology cause 31 % of economical losses, but 55 % of fatalities at the global scale. In Europe these numbers are 20 and 23 %. Globally wet storms are the most dangerous (25 % in the losses, i.e. equally dangerous with the floods, and 34 % considering the deaths), whereas in Europe the storms (32 %) and the hydrological extremes (25%) cause the most losses, but 55 % of the fatalities were caused by the heat waves.

Europe-mean (EU+5 countries) 1980-2009 (EEA, 2010). (The grey-scaled colours, arranged in clock-wise order in the diagrams, correspond to left-to-right and then up-to-down order in the below-listed legends.)***

The recent IPCC SREX Report (2011) assesses how exposure and vulnerability to weather and climate events determine the impacts and the disaster risk. It also evaluates the influence of natural climate variability and anthropogenic climate change on climate extremes. It also considers the role of development in trends in exposure and vulnerability, implications for disaster risk, and interactions between disasters and development. The Report examines how disaster risk management and adaptation to climate change can reduce exposure and vulnerability to weather and climate events and thus reduce disaster risk, as well as increase resilience to the risks that cannot be eliminated.

The construction of the Report is presented in *Fig. 2*, which is also a good multidisciplinary comprehension of the whole issue.

2. DEFINITION OF WEATHER AND CLIMATE EXTREMES

The IPCC WG-I (2007) Glossary writes "An extreme *weather event* is an event that is rare at a particular place and time of year. Definitions of *rare* vary, but an extreme weather event would normally be as rare as or rarer than the 10th or 90th percentile of the observed probability density function." Later, it also states "When a pattern of extreme weather persists for some time, such as a season, it may be classed as an *extreme climate event*, especially if it yields an average or total that is itself extreme (e.g., *drought* or heavy rainfall over a season)."

To the author's view, this compilation is a limitation compared to of the way how the term "climate extreme" is most often used. The difference is that monthly or seasonal temperature anomalies can well be beyond the above rarity limit, even if they do not cover any day with a weather extreme. Furthermore, monthly or seasonal excess water may well be combined by moderate, but repeated diurnal precipitation amounts, as well.

The IPCC SREX (2011) defines the topic in its SPM (page 2.), as follows: „Climate Extreme (extreme weather or climate event): The occurrence of a value of a weather or climate variable above (or below) a threshold value near the upper (or lower) ends of the range of observed values of the variable. For simplicity, both extreme weather events and extreme climate events are referred to collectively as 'climate extremes'." Unfortunately, this definition is even less exact and bears both above problems of the IPCC (2007) definition.

Hence, for the purpose of this paper, we define extreme events as follows: *Meteorological extremes* are events that are rare and have high impact. Both rarity and impact are needed for an event to to be considered a meteorological extreme e.g. the permanent drought in Sahara (not rare) or the amazing optical phenomena (no impact) are not considered meteorological extremes.

An event has high impact by virtue of its intensity or duration. *Weather extremes* are the rare events that are of high impact mainly due to the intensity of one or more observed atmospheric variable. By contrast, *climate extremes* are those rare periods of time that have high impact due to the sustained duration of one or more observed atmospheric variable. More detailed distinction is given below.

2.1 Weather extremes

The professional surface-based observations of the Global Observing System provide weather measurements, including air temperature, wind speed, wind direction, precipitation, cloud cover, humidity, sunshine hours and visibility, etc. taken regularly over the Globe. Firstly, we list the extreme weather events from the so-called synoptic codes, which indicate the events that are worth observing and archiving.

In codes *(http://www.srh.noaa.gov/jetstream/synoptic/ww_symbols.htm)* by WMO for the observations, the candidates for extremity, depending on their frequency and impact, are as follows: *Haze, mist, fog, dust whirl, sand whirl, duststorm, sandstorm, freezing rain, ice fog, ice needles, ice sleet. drifting snow, blowing snow, depositing rime ice, rain shower, snow shower, shower of hail, thunderstorm (observed lighting and thunder), squall lines, funnel cloud, tornado.*

Having the continuous thermodynamic state indicators, above or below a certain frequency and/or impact threshold is another class of extremes, e.g. temperature below zero, or rainfall above 20 mm. These are also weather extremes.

The environmental extremes, e.g. avalanches, forest fires or strong coastal waves, are at least affected by meteorological extremes, but are not considered in our study. Despite our present scope, the operational warning practice tries to provide information even about these mixed events, too.

2.2. Climate extremes

By the above definition, climate extreme is a longer-term (monthly or seasonal) mean or frequency of variables or events, which are rare of potentially high impact. The climate extremes may be time averages or frequencies of events above a given diurnal threshold of a single meteorological variable. These averages or frequencies are often combined into *univariate indices*. Typical indices include the number or fraction of cold/warm days/nights etc. above the 10^{th} percentile, or the 90^{th} percentile, generally defined with respect to a pre-selected reference period.

In 1998, a joint WMO-CCl/CLIVAR Working Group formed with the purpose of climate change detection. One of its task groups aimed to identify the climate extreme indices and completed a climate extreme analysis over the world where appropriate data were available. These indices are given in more recent source by van Engelen et al., (2008), see *http://eca.knmi.nl/indicesextremes*. Another set of indices including uni- and multivariate indices, used in most of the European countries, is listed by Eitzinger et al, (2008). Some other examples are wind-based (Della-Marta et al., 2009) or pressure-based (Beniston, 2009) indices.

Extremity of weather or climate and the effects caused by them are often too complex to be expressed by a single meteorological variable. In other words, these climate extremes occur in the multi-dimensional phase-space of variables. Using more variables, however, does not establish a linear sequence of the extremities. Hence, most often the multivariate extremities are arranged into a single index.

For example, the thermal comfort index is calculated by means of the *physiologically equivalent temperature*, PET, based on the human energy balance (Matzarakis et al., 1999). For calculating this weather extreme, four meteorological parameters (air temperature, relative humidity, wind speed and cloudiness) as well as some assumed physiological parameters are used.

3. CLIMATE CHANGE AND THE EXTREMES

3.1 Expectations of changes in the extremes

Statistical and physical considerations suggest that a warmer climate bears more meteorological extremes than the present one. Later, we refer to some further difficulties that hamper the unequivocal establishment of the trends in the extremities.

Statistical considerations. Frequency of an extreme event can generally be enhanced under climate change for two reasons. When the whole distribution is shifted in one direction, with no change in the variance, then the extremes of this direction become more frequent, whereas the opposite extremes become less frequent. In the second case, when variance of the distribution changes with no shift in the mean, frequency of extremes on both sides changes in the same direction. Of course, parallel occurrence of the two causes is also possible.

Three metrics can be considered to quantify the trends in the extremes. One of them is to count the number of record-breaking events in a given year. However, it may well happen that hot extremes are setting new records, while cold extremes become less frequent. In such a case, counting the records would probably not indicate a significant trend, though frequency of the opposing extremes changed a lot.

Besides counting the single events, the fraction of a given territorial unit can be summarized according to the distribution of local absolute records or probability of falling into a rare category (e.g. lower 10 %). Trends of these fractions may also be established. A shortcoming of this approach is that it requires equal levels of data coverage for the whole area. In many cases, however, this condition is not fulfilled, especially in case of rapid, small-scale weather extremes.

A third approach arises from the fact that extremes often have deleterious economic consequences. The global costs of extreme weather events are already high and rising. It may therefore be possible to measure the integrated economic effects of extremes by the insurance payout as a function of time. However, besides the effects of inflation, this measuring tool would also be influenced by changes in the vulnerability of the insured properties, e.g. by their age, or by their changing exposure in connection with the number of inhabitants or users of the real estate.

The statistical trends should better be supported by physical explanations.

Physical considerations. Some physical processes support the hypothesis of increasing extremities parallel to global warming, but some others definitely question that. The most frequent argument for the more intense extremes is the increased energy content of the climate system, including the atmosphere (IPCC WG-I, 2007, Fig. 5.4). Having more thermodynamic energy in the whole system, the energy may be more easily cumulated in a given atmospheric object and region.

Another reasonable assumption is that in a warmer world, water vapour content of the air column is higher (IPCC WG-I, 2007: Figures 3.20 and upper Figure of 3.21), hence more latent heat may develop and turn into kinetic energy, especially via convection. A third experience is that in a warmer world the average lapse rate is higher, which in turn also support the formation of convective systems.

Other considerations, however, may cause less intensive extremes. E.g., the experience that the high-latitudes and the continents warm faster than the lower latitudes and the oceans, leads to smaller horizontal temperature- and, hence, pressure gradients generally become weaker in the process of global warming-up.

3.2. Data quality, free oscillations, conceptual problems

Establishing trends in extremities is difficult due to at least three problems. They are the uneven quality of observations (data problems), a conceptual problem, since scientists often search the trends in function of time, sometimes mixing the globally warming, stagnating and cooling periods and the existence of long-term free oscillations which make it difficult to detect the appearance of extreme events.

The data problem. Near-surface temperatures are generally influenced by various local disturbances (developing cities, vegetation), modifications in the observation technology (changes of time, instrumentation or shading devices) or simply relocation of the weather (climate) station. In some other cases, e.g. for the tropical cyclone records, the completeness of observations is rather heterogeneous due to changing observation technology and reporting protocols.

A conceptual problem. The third problem, making empirical trend analyses very difficult, is the mechanistic computation of statistical trends for any long period of time. Very often, these periods join globally warming periods, together with no change, or even with cooling periods. One may assume that a given behaviour of the extremities in a warming period should not be the same as in a stagnating or cooling period. Hence, any meaningful trend estimation should consider monotonously warming, or cooling periods, otherwise nothing can be told about possibilities of their extrapolation. (In principle, the extrapolation is never sure, but it is more likely if established in a similarly warming period, expected for the future.)

The free oscillations problem. Climate also fluctuates randomly, with relatively long, but irregular cycles. *Fig. 5* presents such fluctuations at the high latitudes of Northern Hemisphere. The three periods of 12, 7 and 6 years of duration indicate very different distribution of temperature anomalies. These natural fluctuations make the detection and attribution of changes in the extremities very difficult.

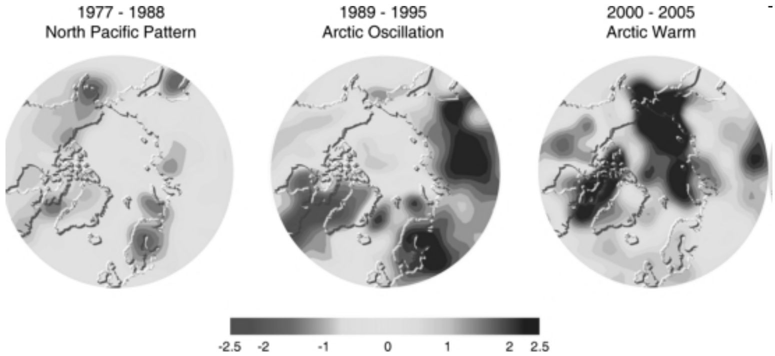

Fig. 3. Arctic temperature anomaly patterns as examples of strong inter-annual variability within a monotonously warming period at the global scale. Data from NO-AA/ESRL, http://www.cdc.noaa.gov/cgi-bin/Composites/ printpage.pl [6 April 2007] Positive temperature anomalies are found over Canada (1977-1988), Eurasia (1989-1995) and over the majority of the Polar region except the cooler than average mid-Canada (2000-2005). Negative anomalies are fould in wide areas of Eurasia (1977-1988), ocean areas attached to Northern Canada (1989-1995).

3.3. What is seen from the research?

Tab. 1 displays the major extreme events, indicating the 20th century tendencies, likelihood of human contribution in the observed trend and likelihood of the future trends. It indicates „warmer and fewer cold days and nights”, as well, as „warmer and more frequent hot days and nights”, detected over most land areas. Both statements are assessed “very likely” with over 90 % of probability concerning their 20th century trends and over 2/3 of probability for “likely” anthropogenic component in it. For the future, the continuation of the trends is virtually certain (99 %). Heavy precipitation events at the temperate latitudes and increase of drought affected area is likely in many regions since 1970s with “more likely than not” assessment its the anthropogenic component. Continuation of the increasing area in the 21st century is “likely”.

Recently, the IPCC SREX Report (2011) mainly approved these statements. E.g,, changes in return periods of the 20 years thresholds in diurnal maximum temperatures and in daily precipitation are displayed in Figs SPM 4A and 4B, for 26 continental regions between two future periods and 1981-2000. For Central Europe they indicate 4-6 times more frequent occurrence in the thermal and ca. 1,5x in the precipitation extreme by 2045-2065, depending on the assumed emission scenario.

Though it is very likely (IPCC WG I, 2007) that, at least in the recent four to five decades, mankind significantly contributed to global warming. Hence, these decades are fair natural experiments reflecting the similar causes of warming to that which will likely drive the next several decades. Nevertheless one cannot be sure that all trends found in the recent decades will be valid for the future too. This question can be assessed by combining modelling and statistics in the attribution studies that already tackle the extremes (Min et al., 2011).

Tab. 1. Recent trends, assessment of human influence, and projections of extreme weather events. (IPCC WG-I, 2007: Tab. SPM-2)

Phenomenon and direction of trend	Likelihood that trend occurred in late 20th century	Likelihood of human contribution to observed trend	Likelihood of trends projected for 21st century)
Warmer and fewer cold days and nights over most land areas	*Very likely*	*Likely*	*Virtually certain*
Warmer and more frequent hot days and nights over most land areas	*Very likely*	*Likely (nights)*	*Virtually certain*
Warm spells/heat waves. Frequency increases over most land areas	*Likely*	*More likely than not*	*Very likely*
Heavy precipitation events. Frequency (portion of total) mostly increases	*Likely*	*More likely than not*	*Very likely*
Area affected by droughts increases	*Likely* in many regions since 1970s	*More likely than not*	*Likely*
Intense tropical cyclone activity increases	*Likely* in some regions since 1970	*More likely than not*	*Likely*
Increased incidence of extreme high sea level (excludes tsunamis)	*Likely*	*More likely than not*	*Likely*
